## Feasibility studies for various examples of AirHES

## Baseline:

1. Getting water from fog (minimum estimation)

- According to Chilean plants : 3-13 L/m2/day
- According to FogQuest : 5-25 L/m2/day
- According to LWC for fog $(0.05 \mathrm{~g} / \mathrm{m} 3)$ at wind speeds near the ground in the mountains $\sim 5$ $\mathrm{m} / \mathrm{s}$ and mesh efficiency $\sim 50 \%: 10.8 \mathrm{~L} / \mathrm{m} 2 /$ day (by calculation)
We can see that the calculated data agree well with the experimental data for passive fog collectors. Thus, if we take these data as a basis for estimates of minimum water collecting in the clouds, we can take $10 \mathrm{~L} / \mathrm{m} 2 /$ day as a lower limit in the feasibility study.

2. Getting water from the clouds (average estimation)

- According to active (omni-directional) highland fog collectors (really similar to clouds) : 160-300 L/m2/day
- According to LWC for stratus and cumulus clouds $(0.25-0.45 \mathrm{~g} / \mathrm{m} 3)$ at wind speeds at a height of clouds $\sim 10 \mathrm{~m} / \mathrm{s}$ and mesh efficiency $\sim 50 \%: 108.0-194.4 \mathrm{~L} / \mathrm{m} 2 /$ day (by calculation)

We can see that the calculated data agree well with the experimental data for active (omnidirectional) fog collectors, which are similar to AirHES. Thus, if we take these data as a basis for estimates of average water collecting in the clouds, we can take $100 \mathrm{~L} / \mathrm{m} 2 /$ day as a base value in the feasibility study.
3. Getting water from the clouds (maximum estimation)

- According to LWC and scientific observations for cumulonimbus and thunderclouds (1-3 $\mathrm{g} / \mathrm{m} 3$ ) at wind speeds at a height of clouds $\sim 15 \mathrm{~m} / \mathrm{s}$ and mesh efficiency $\sim 50 \%: 648-1944$ L/m2/day (by calculation)

Thus, if we take these data as a basis for estimates of maximum water collecting in areas of high rainfall (in the equatorial zone, as well as in southern India and China), we can take $1000 \mathrm{~L} / \mathrm{m} 2 /$ day as the upper limit in the feasibility study.

## Scientific prototype

This is a minimal device used for obtaining experimental data to collect water from the clouds and for verification of design solutions. Like fog collector study we can use the SFC (standard fog collector, 1 m 2 ). Such device has been tested on Seliger 13/07/30 with the rise to a height of $\sim 1.5$ km , but during descent the rope was broken and device was destroyed. Tests have shown that an alternative design based on the kite may have the advantage due to the use of aerodynamic lift forces, but the design is a need for more detailed and complex aerodynamic calculations (XFlow, ANSYS, etc.). Hydraulic calculation is performed to find the minimum hose diameter that allows this stream to flow in waterfall mode (i.e., such a diameter that corresponds to equal flow resistance and small hydraulic head on a part of hose, for example, a length of $10 \mathrm{~m}=1 \mathrm{~atm}$ ). Calculation in the table is given for a height of 2 km . To estimate the aerodynamic lift of the kite used simplified formula $0.04 * \mathrm{~V}^{2} * \mathrm{~S}$ at wind speeds of 5 and $10 \mathrm{~m} / \mathrm{s}$. To assess the aerostatic lift of the balloon is assumed that every m 3 of hydrogen or helium corresponds approximately 1 kg weight.

## Minimum technical prototype

It's a full technical plant, which will allow at minimum cost to check the design elements and feasibility study of the concept AirHES. It differs from the scientific prototype that it contains the penstock (pressure hose), the hydraulic turbine (or hydraulic motor) and generator. When calculating the thickness of the wall of the hose (reinforced by dyneema with an estimated strength of 2.4 GPa ) used a 5 -fold margin of safety. The hose plays also the role of a rope, which can be verified in the most intense upper point where the calculated margin of safety is equal to 9.25 in all variants. Expected lifetime of plant - 10 years.

## Further increase of power

In principle, the same pattern can be calculated and for the next generation - high power module with a network of $\sim 1 \mathrm{~km} 2$. However, we already reach the limit values for the size of balloons and kites. To go to this power, we should change the design solutions. For example, we can use the meshes themselves as kites to support the basic weight of the produced water in the hose, and to use the balloon only to support meshes and empty hose in complete calm. This will demand the creation of an appropriate control system (preferably by using a natural physical feedback), which will monitor wind speed and emergency dumping or spraying water from the hose under the threat of falling. Here is an example calculation of the feasibility study of such plant.

| Water collection rates, L/m2/day | 10 | 100 | 1000 |

This also should include the need to develop a system of the automatic and interconnected accumulation of the water storage upstream and the hydrogen in ballonet balloons that will significantly reduce meteo-dependence of AirHES without using external storage (which dramatically increase the cost of wind and solar plants).
Finally, for GW plants it can be quite cost-effective construction of vertical pressure tube (or even waterfall tube) height of 1-2 km with feeding from located around the meshes with total size of tens of square kilometers.

## Irrigation project

This is a special plant that can produce rain in arid areas for creating an oasis in the desert or rain over anhydrous island (like Malta, for example). It has no hose, but may have elements of the drainage system for generating a jet of water to reduce evaporation of rain on the way to the ground. It may be made both through the balloon (possibly by using icing effect on high altitude), and on the basis of the kite (then possible to use only at positive temperatures, which restricts the height and, accordingly, the area coverage of such plant).

Let's estimate, for example, the area of mesh of irrigation AirHES to create an oasis in some place in the Sahara desert. For example, take the meteorological data for the year to Egypt - Wadi El Rayan. It is seen that there is practically no rain, but the clouds for the year can be estimated at $10 \%$. On ARL sounding diagram, we can estimate the height of the clouds about 4 km . With a typical deviation from the vertical $\sim 15$ degrees we obtain the irrigation area about 3 km 2 . If we want to create a comfortable area there with average level of precipitation on the planet $\sim 1 \mathrm{~m}$ per year, this gives a flow $\sim 8200 \mathrm{~m} 3 /$ day, which for the average estimation by getting the water out of the clouds gives the mesh area 82000 m 2 , and taking into account $10 \%$ of meteorological evaluation of cloudiness increases this size an order of magnitude to 0.82 km 2 .

## Project for drinking water supply

This is probably the most profitable startup project for all variants of AirHES. This plant is similar to the irrigation project, but differs in that has hose with a gravity flow (like a scientific prototype). Since such hose in essence is just a channel of waterfall, it should not withstand the pressure of the water column at 2 km . Balloon must keep its own weight, the weight of hose with flowing water, and the weight of the meshes with residual water. With calculating the hose from dyneema with 5fold margin of safety at the top of hose it is necessary to consider only its own weight and the weight of flowing water in it.
Consider, for example, water supply of Malta (452 thousand people), the only state which does not have its own fresh water. Meteorological data show that excepting the two summer months in the rest of the time over Malta there is normal distribution of the clouds, however Malta has no high mountains and therefore has no natural sources of fresh water.
